Received 24 May 2007/Accepted 27 August 2007

Human immunodeficiency virus type 2 (HIV-2) infection leads to a lifelong asymptomatic period in the majority of patients. Even in patients with progressive disease, a slow CD4 count decline characterizes the chronic phase of HIV-2 infection, suggesting that peripheral T-cell homeostasis is controlled better following HIV-2 infection than following HIV-1 infection. Herein we showed that, in contrast to HIV-1-infected patients, HIV-2-infected patients demonstrate enhanced thymic function compared to age-matched healthy individuals. The correlation between higher thymic production and lower CD4 T-cell loss in these patients suggests that efficient thymopoiesis is implicated in the long-lasting maintenance of CD4 T-cell counts in HIV-2 disease.

Human immunodeficiency virus type 2 (HIV-2) infection is associated with a more benign course of disease than HIV-1 infection is. The majority of HIV-2-infected individuals remain asymptomatic for years following infection and their disease behaves like that of HIV-1-infected long-term nonprogressors, while the patients who progress to disease exhibit a much slower rate of CD4 decline than the rate for HIV-1-infected patients (9, 12, 21). The latter group of HIV-2-infected patients is reminiscent of HIV-1 slow progressors, characterized by a slow CD4 T-cell decline despite detectable viremia (3, 13). Furthermore, studies in geographic areas where high HIV-2 prevalence is observed demonstrated that the life expectancy for individuals with HIV-2 infection is often close to that of uninfected individuals living in the same villages (12). The factors determining the delayed disease progression in HIV-2 infection remain largely unknown (14). Although plasma viral load is much lower in HIV-2 infection than in HIV-1 infection (2), the proviral loads of HIV-2-infected patients are similar to those of HIV-1-infected patients at the same disease stage (10, 11), suggesting that the two viruses do not differ significantly in their ability to establish infection and replicate in human cells (1, 17).

On the other hand, similar degrees of T-cell hyperactivation, as well as increased T-cell cycling, were observed for both HIV-1- and HIV-2-infected patients with similar degrees of CD4 depletion (18). This suggests an intimate link between generalized immune activation and associated cell death and CD4 depletion in both infections despite distinct viremias and clinical outcomes.

HIV-1 infection is associated with an impairment of intrathymic precursor T-cell proliferation resulting in a huge reduction of de novo T-cell production thought to participate in the progressive decline of peripheral CD4 T-cell counts, in particular in the recent thymic emigrants (RTEs) and naïve T-cell compartments (4). An imbalance between production and destruction of peripheral CD4 T cells would lead to their progressive decline over time and eventually to AIDS (5, 6). However, in slow progressor HIV-1-infected patients, we recently demonstrated that the maintenance of circulating CD4 T cells is strongly associated with efficient thymopoiesis (3).

We thus hypothesized that the maintenance of de novo T-cell production may counteract the peripheral CD4 loss that is known to occur in HIV-2 infection and represents a major mechanism underlying the slow progression of HIV-2 disease. Here we analyzed the role of thymopoiesis in the long-term maintenance of peripheral CD4+ T-cell numbers in a cohort of untreated chronically HIV-2- and HIV-1-infected subjects currently living in Portugal and attending outpatient clinics in Lisbon, Portugal, compared to age-matched healthy individuals. A summary of the clinical features of the patients studied and healthy controls is shown in Table 1.

Thymic activity was estimated by measurement of the intrathymic proliferation history of circulating RTEs by quantification of the signal joint/beta T-cell receptor excision circle (sj/βTREC) ratio as described previously (3, 4, 20). This marker, which is independent of peripheral T-cell proliferation and death rate, directly reflects the number of proliferation cycles undergone by precursor T cells during their intrathymic differentiation and thus thymic output (4). Surprisingly, while in both HIV-1 and HIV-2 patients, the younger individuals (35 to 45 years old) demonstrate a low thymic function (median sj/βTREC ratios of 11.3 and 6.5 for HIV-1 and HIV-2 patients, respectively, compared to a ratio of 24.1 in the healthy control group [P = 0.026 and P = 0.02, respectively]; Fig. 1A), a significantly higher sj/βTREC ratio characterizes HIV-2-infected subjects that were >45 years old compared to healthy controls (median sj/βTREC ratio of 17.0 in HIV-2-infected patients compared to 4.9 in control individuals [P = 0.0047]; Fig. 1A). This contrasts with the expected low intrathymic proliferation observed in age-matched HIV-1-infected patients (sj/βTREC ratio of 6.9). In fact, analysis of the sj/βTREC ratio

as a function of age shows that the expected age dependence of thymic output is not observed in the HIV-2-infected patients (Fig. 1B). While most patients with chronic HIV-1 infection demonstrate a rapid and persistent defect in thymic output (3, 4), the impairment of thymopoiesis observed in the younger groups of HIV-2-infected patients is not further exacerbated by aging. In contrast, it seems that this function is maintained in this group of patients, so that in aged individuals, the sj/βTREC ratio becomes greater than in healthy individuals, most likely leading to long-term sustained thymic output.

To assess the impact of our observations on the peripheral RTE subset, we evaluated the frequency of sjTREC-containing cells (sjTREC/10⁵ cells) in peripheral blood mononuclear cells from all patients studied. A significant reduction of the sjTREC-positive cell frequency was shown in HIV-2-infected patients compared to the control group (median sjTREC/10⁵ cells of 102 and 297, respectively; \( P = 0.001 \) in HIV-2 and controls). However, this reduction was mainly observed in younger (35- to 45-year-old) individuals (median sjTREC/10⁵ cells of 558 and 148, respectively; \( P = 0.007 \) in HIV-2 and controls; Fig. 2A). In contrast, despite lower CD4 T-cell counts (Table 1), older individuals (>45 years old) had RTE counts similar to those of age-matched controls (Fig. 2A), supporting our previous assumption that the increased thymic output translates into sustained circulating RTE frequency.

Nevertheless, one must consider that the assessment of sjTREC frequency may be influenced by variable degrees of immune activation/proliferation in the groups studied. We thus also determined the sjTREC concentration (sjTREC/ml of blood) which, although influenced by thymic output and RTE survival, does not depend upon the general state of immune activation/proliferation (7, 8).

Interestingly, the analysis of the sjTREC concentration also showed that the patients that were >45 years old behave like age-matched controls do, with a significant reduction characterizing 35- to 45-year-old individuals (median sjTREC/ml of blood) which, although influenced by thymic output and RTE survival, does not depend upon the general state of immune activation/proliferation (18, 19). It is thus most probable, as demonstrated by Sieg et al. in HIV-1 infection that T cells expressing activation/proliferation markers (CD69, HLA-DR, Ki-67 . . .) in HIV-2 infection are also determined to...

### FIG. 1. HIV-2-infected patients demonstrate high thymic function.

(A) The sj/βTREC ratio, a measure of thymic activity, was calculated for healthy individuals (controls [Ctrls]) and HIV-1- and HIV-2-infected patients. The three groups were subdivided into groups by age (35 to 45 years old and >45 years old). Gray symbols represent healthy control individuals of African origin. Statistical differences (\( P \) values) between the different groups are shown above the values (Mann-Whitney test). NS, not significant. (B) Correlation between the sj/βTREC ratio and age in healthy controls (white and gray symbols, representing Caucasian and African individuals, respectively, and HIV-2-infected patients (black symbols). Spearman’s correlation and associated probability are shown for the control group.
die rapidly in vivo (15, 16). This is further emphasized by analyzing the relationships between the sj/TREC ratio (thymic production) and the sjTREC concentration (approximate RTE counts). As expected, both parameters correlated nicely in the control group and the HIV-1-infected patients ($r = 0.574$ and $P = 0.006$ and $r = 0.653$ and $P = 0.014$, respectively [Fig. 2C, left graph]). In contrast, in HIV-2-infected patients, thymic production was not associated with RTE concentration (Fig. 2C, right graph), demonstrating that the sustained thymic function in older HIV-2-infected patients does not lead to the expected enlargement of the TREC-rich T-cell population, likely being concomitantly expanded by increased cell death and/or accelerated maturation. This is further emphasized by the absence of correlation between circulating interleukin 7 levels and sjTREC quantification in HIV-2-infected patients (1).

In order to estimate the impact of the observed enhanced thymopoiesis on the relative resistance to disease in the HIV-2-infected patients, we calculated the rate of CD4 count decline in this group of patients over a median period of 2.5 years preceding the analysis of thymic function. In HIV-2-infected patients, the sj/βTREC ratio tends to correlate with the variations in CD4 T-cell counts over time ($r = 0.432$ and $P = 0.09$; Fig. 3A). Such a correlation does not exist in the HIV-1-infected patients ($r = 0.06$ and not statistically significant). Interestingly, when classifying the patients according to their sj/βTREC ratio, a significant difference was observed in their capacity to maintain CD4 T-cell counts over the follow-up period. While patients demonstrating efficient thymopoiesis (i.e., sj/βTREC ratio of >10) preserve their CD4 T-cell counts over the follow-up period (median CD4 change of +25 cells/...
year [range, −43 to +202]; Fig. 3B), patients with low sj/βTREC ratio (<10) show a slow but definite decline in circulating CD4 T-cell numbers (median loss of −40 cells/year [range, −217 to +19; P = 0.023]). In contrast, in the HIV-1-infected group, the extent of intrathymic precursor T-cell proliferation does not correlate with CD4 T-cell decline (median CD4 changes of −122 and −73 cells/year in patients with sj/βTREC ratios of <10 and >10, respectively; not statistically significant; data not shown).

Taken together, these data demonstrate that patients with chronic HIV-2 infections maintain thymic production for prolonged periods of time, even after they reach 45 years of age, when significant thymic involution is observed in healthy individuals. This effect, reminiscent of what was observed in HIV-1-infected slow progressors, suggests that increased CD4 T-cell death can, at least partly, be compensated for by an overproduction of new T cells in HIV-2-induced pathology. The fact that younger HIV-2-infected patients demonstrate a reduced thymic function suggests either that HIV-2 infection can lead to various levels of pathogenesis or that sustained thymic function in aging patients is a mechanism that develops slowly to compensate for increased cell death. Patients who cannot maintain thymic function would exhibit progressively lower CD4 T-cell counts, eventually leading to AIDS, while others whose thymus remains functional maintain CD4 counts and remain asymptomatic for several decades. However, it is possible that efficient thymopoiesis is both a cause and consequence of limited pathogenicity in HIV-2. It is quite possible that low viral loads in HIV-2-infected patients, by inducing limited homeostatic perturbations, leads to maintained thymic potential and that when lymphopenia occurs, this capacity of the thymus to produce new T cells allows the maintenance of CD4 counts and naïve T-cell diversity sufficiently high to limit progression of the disease.

Interestingly, Poulsen et al. observed that in some West African villages, older people (55 to 80 years of age) with HIV-2 infection have the same mortality risk as uninfected individuals do (12). The capacity of these patients to maintain de novo T-cell production through efficient thymopoiesis despite aging may participate to their longevity in the presence of HIV-2 infection. These new data on the role of the thymus in this natural model of attenuated HIV infection bring new arguments to the contribution of ongoing thymopoiesis for HIV pathogenesis and the rate of progression to AIDS and strengthen the importance of the thymus as a target for immune-based therapies.
