KEYWORDS

anthropogenic noise, behaviour, freshwater ecosystems, functional response, *Phoxinus phoxinus*

Abstract

1. Anthropogenic noise can affect animals physically, physiologically and behaviourally. Although individual responses to noise are well documented, the consequences in terms of community structure, species coexistence and ecosystem functioning remain fairly unknown.

2. The impact of noise on predation has received a growing interest and alterations in trophic links are observed when animals shift from foraging to stress-related behaviours, are distracted by noise, or because of acoustic masking. However, the experimental procedures classically used to quantify predation do not inform on the potential demographic impact on prey.

3. We derived the relationship between resource use and availability (the functional response) for European minnows (*Phoxinus phoxinus*) feeding on dipteran larvae (*Chaoborus* sp.) under two noise conditions: ambient noise and ambient noise supplemented with motorboat noise. The shape and magnitude of the functional response are powerful indicators of population outcomes and predator – prey dynamics. We also recorded fish behaviour to explore some proximate determinants of altered predation.

4. For both noise conditions, fish displayed a saturating (type II) functional response whose shape depends on two parameters: attack rate and handling time. Boat noise did not affect handling time but significantly reduced attack rate, resulting in a functional response curve of the same height but with a less steep initial slope. Fish exhibited a stress-related response to noise including increased swimming distance, more social interactions and altered spatial distribution.
5. Our study shows the usefulness of the functional response approach to study the ecological impacts of noise and illustrates how the behavioural responses of predators to noise can modify the demographic pressure on prey. It also suggests that prey availability might mediate the negative effect of noise on predation. Community outcomes are expected if the reduced consumption of the main food sources goes with the overconsumption of alternative food sources, changing the distribution pattern of interaction strengths. Predation release could also trigger a trophic cascade, propagating the effect of noise to lower trophic levels.

1 INTRODUCTION

Anthropogenic (man-made) noise is recognized as a pervasive pollutant, changing the soundscape of many ecosystems. It has been found to affect the anatomy, physiology and/or behaviour of both invertebrates and vertebrates in several ways, with consequences ranging from discrete, short-term behavioural adjustments to fitness reduction through decreased reproduction or survival (Popper & Hastings, 2009; Kight & Swaddle, 2011; Shannon et al., 2016). Noise is therefore likely to alter key ecological interactions like competition, parasitism or predation, with potential consequences on species coexistence, community stability and ecosystem-level processes (Kunc et al., 2016; Sabet et al., 2016). Although large-scale effects are highly expected, documented impacts rarely exceed individual responses.

By driving energy through food webs and affecting biodiversity, trophic interactions influence ecosystem functioning. Noise is likely to alter the strength of a trophic interaction and hence energy flow in many ways. A common reaction is that predators are stressed by noise and shift from feeding to other activities like hiding, escaping or interacting with conspecifics (Cox et al., 2018). Energy flow can also decrease when the auditory cues used to
locate prey are masked (Schaub et al., 2008), or when prey perceive noise as predation risk and become more vigilant (Rabin et al., 2006). Alternatively, energy flow can increase when prey are distracted and become more vulnerable to predation (Chan et al., 2010), or when noise masks the acoustic cues involved in predator recognition (Kern & Radford, 2016).

Despite the increasing number of experimental studies reporting noise-modified trophic interactions (Cox et al., 2018; Slabbekoorn et al., 2018), predicting their ecological significance in terms of population dynamic and species coexistence remains difficult. This comes partly from the experimental designs and the predominant use of ‘snapshot’ predation tests, typically when a predator either alone or in group is presented to a single prey density.

Although snapshot predation tests provide a rapid and effective method to quantify predation, they do not inform on the potential demographic impact on the prey and, so importantly, results can depend on the prey density chosen (see Fig. 2 in Dick et al., 2014).

Deriving the functional response (FR), which is the relationship between resource use and resource density (Solomon, 1949; Holling, 1959a), offers an alternative and complementary approach to snapshot predation tests. Interestingly, the shape and magnitude of the relationship (i.e. the FR curve) are powerful indicators of the strength of top-down control (Dick et al., 2014; Cuthbert et al., 2018). *Per capita* predation rate typically increases with prey availability and three broad shapes of FR are frequently observed: the linear type I, the saturating type II with a decelerating increase up to predator saturation, and the sigmoidal type III with acceleration first at low prey densities and then deceleration towards saturation (Holling, 1959a; Murdoch & Oaten, 1975). In terms of predator – prey stability, type II FRs are characterized by a high proportional consumption at low prey densities that can lead to unstable boom-burst population dynamics whereas the S-shape of type III FRs offers low-density refugia for prey, which prevents such unstable dynamics (Murdoch & Oaten, 1975; Juliano, 2001; Gentleman & Neuheimer, 2008; Kalinkat et al., 2013). The FR approach
provides an experimental framework to test context dependencies in consumer – resource interactions. It has received a growing interest in the fields of fundamental ecology, parasitology and invasion ecology, but remains largely ignored by the ecologists interested in the ecological impact of anthropogenic noise. Very recently, Villalobos-Jiménez et al. (2017) reported decreased magnitude in the FR of damselfly larvae (*Ischnura elegans*) towards cladoceran prey with underwater noise compared to more silent conditions, but no such investigations have been carried out in vertebrates.

Our aim was to test the effect of anthropogenic noise on the shape and magnitude of the FR of a freshwater fish, the European minnow *Phoxinus phoxinus*, feeding on dipteran prey. European minnows have a wide distribution range throughout the Palaearctic region and inhabit the cold and well-oxygenated waters of fast-flowing mountain streams, large lowland rivers and lakes (Kottelat & Freyhof, 2007; Vucić et al., 2018). Consequently, they can be exposed to a wide range of anthropogenic noise including recreational shipping in small lakes and industrial noise in large rivers (Voellmy et al. 2014). In our study, fish were presented to six prey densities under the conditions of ambient or motorboat noise, and we measured swimming distance, spatial distribution and social interactions through the distance to a companion fish to explore the link between FR and behaviour. In the control condition of ambient noise, we expected the FR of minnows to be of type II, which is the FR type usually displayed by fish in low-complexity environments (i.e. no shelter provided, Alexander et al., 2014, 2015; Laverty et al., 2017). The two key parameters of a type II FR are the attack rate $a$ and the handling time $h$. Attack rate is a measure of predator’s efficiency at low prey densities and defines the shape of the FR curve: the higher the attack rate, the steeper the initial slope. Handling time is defined as the time during which the predator stops searching for prey after a capture (Holling, 1959b). It includes successive stages like prey handling and ingestion and defines the height of the FR curve: the lower the handling time, the higher the asymptote.
Using another experimental approach, Voellmy et al. (2014) reported that *P. phoxinus* exposed to the additional noise produced by shipping consumed significantly fewer live *Daphnia magna* and exhibited stress-related behaviours, including increased inactivity and more social interactions. From this, we can give some predictions on the FR with noise and on the link between behaviour and FR parameters. Because predator–prey encounters are expected to increase with predator mobility (Gerritsen & Strickler, 1977), a smaller swimming distance resulting from increased inactivity should reduce attack rate. This effect should be even greater at low prey densities, when prey are scarce. Predator–prey encounters should also increase with the area covered by predators. If noise makes fish swim closer to the companion fish because they are looking for more social interactions, or triggers any bias toward a particular area of the aquarium for instance to avoid the sound source, then it should decrease attack rate. More social interactions could also reduce attack rate simply because they are associated with a lower motivation for feeding. Concerning handling time, it has a behavioural component but also depends on morphological and physiological constraints. If the noise minnows were exposed to is unlikely to alter their anatomy or physiology, it could distract them during prey handling and ingestion, resulting in increased handling time. We therefore expected a slight decrease in the height of the FR curve possibly due to a predator distraction effect during prey handling, and a more pronounced decrease in the initial slope because of a smaller attack rate, leading to a less steep type II or a shift towards the S-shape of the type III.

2 METHODS

2.1 Animal collection and maintenance
In March 2018, 70 *Phoxinus phoxinus* (body length = 5.5 ± 0.6 cm) were collected with electrofishing from the Volvon, a small tributary of the Coise river, at Veauche (45°34’12.4”N, 4°18’21.3”E, Loire, France), and transported to a breeding room of ENES Laboratory thermoregulated at 17°C with a 12:12 light:dark regime. We considered this population as naïve regarding motorboat noise. We did not control for sex and there was no gravid female at this period of the year. Fish were housed for 20 days in a 300 L plastic tank (housing tank) filled with continuously filtered and aerated dechlorinated tap water, and equipped with shelters. To remove They were fed daily with commercial fish pellets and starved for 24 h prior to experimentation. We used live *Chaoborus* sp. larvae (Diptera, Chaoboridae) as prey. In addition to being part of the diet of *P. phoxinus* (Frost 1943), they are pelagic and do not form aggregates in aquariums, which makes them good candidate prey items for functional response experiments (Médoc et al., 2013, 2015). Between-individual differences in diet might occur in the field, with some fish consuming more dipterans than others, which would induce variability in the results. We used food pellets instead of real prey during maintenance to remove potential search images that some fish might have developed and to make their feeding behaviour more homogeneous. *Chaoborus* sp larvae were purchased from a commercial supplier (www.aquaplante.fr) and maintained in 25 L aquaria under the same conditions than the fish.

### 2.2 Experimental design and protocol

Experiments took place in the breeding room thermoregulated at 17°C with a 12:12 light:dark regime to keep animals under the same conditions. One single fish starved for 24 h was placed in a glass aquarium (60 cm long x 30 cm wide x 32 cm high) filled with ≈ 50 L of filtered and aerated dechlorinated tap water (28 cm water height) and containing a 2-cm layer
of Loire sand. Three sides were covered with black foam rubber panels (15 mm thick) to limit acoustic reverberation whilst one side in the length was left transparent to film the experiment. We inserted an underwater speaker (Electro-Voice UW30, 0.1 to 10 kHz) in the center of the acoustic panel covering the left end of the aquarium (when facing the transparent side). The center of the speaker was 11 cm below the water surface. At the opposite (right) end, we spaced the acoustic panel from the aquarium wall and placed a hydrophone (Aquarian Audio H2A-XLR Hydrophone, frequency response from 10 Hz to 100 KHz) connected to a ZOOM H4next Handy recorder between them to control the sound signal during the experiment. *P. phoxinus* being naturally gregarious (Frost 1943), we provided a companion fish to the focal individual to promote normal behaviour. Companion fish were minnows of standard size (4.7 ± 0.3 cm) used only for this purpose and kept apart from the other minnows in the housing tank. We placed the companion in the center of the aquarium inside a transparent plastic tube (8 cm diameter) to allow visual communication and prevent chemical exchange, and changed it every six experiments. To avoid unexpected sounds that might disturb the experiments, we placed the aquarium inside an acoustic box (‘silent box’, 89 cm long x 78.5 cm wide x 75 cm high) with acoustic foam covering the inner surface, a diffuse light source centered on the aquarium 34.5 cm above the water surface (875 lux light intensity at the water surface, Lux Meter for android devices), one camera (HD-TVI ABUS TVVR33418) facing the transparent side of the aquarium and another one filming from above for behavioural measurements (see below).

Once the focal fish introduced and after a 30-min acclimatization period, the experiment started with the introduction of *Chaoborus* sp. larvae at a single time using a 250-ml glass beaker, trying to cover the entire surface of the aquarium to homogenize prey distribution. Fish resumed their normal behaviour within the three minutes following prey introduction (personal observations) and were allowed to forage for one hour. We tested six
prey densities ($N_0 = 8, 16, 32, 64, 128$ and $256$ larvae in the aquarium) with four replicates per density ($n = 4$) and two noise conditions (see below), which needed 48 fish (plus eight companions) for the whole investigation. Prey densities and experiment duration were fixed based on preliminary experiments in a way to reach predator saturation, avoid predator satiation, avoid total prey consumption, and promote fitting of the functional response models especially at low prey densities. To verify that *Chaoborus* sp. mortality during the experiments was the result of fish predation only, we did four replicates (two per noise condition) of the highest density ($N_0 = 256$) without fish. At the end of each experiment, the focal fish was gently removed with a hand net, measured for fork length and returned to the housing tank separately from the others to prevent reuse. We counted the remaining *Chaoborus* sp. larvae to assess prey consumption and changed the water every two experiments to remove the chemical signals that might have been released by the animals.

The whole investigation needed 13 consecutive days with four successive experiments per day. To balance the time effect, we distributed the experiments in a quasi-systematic way regarding replicates, noise condition and prey densities. At the end of the whole investigation, all the fish were returned to the Volvon.

### 2.3 Noise conditions

As the control noise condition, we played back the ambient noise the fish were exposed to for 20 days in the housing tank. The ambient noise was recorded before storing the fish, using the Aquarian Audio H2A-XLR Hydrophone connected to the ZOOM H4next Handy recorder and placed in the center of the housing tank 14 cm above the water surface (for a 28-cm water depth). After checking the recording to be sure there was no other sounds than water agitation
due to the external pump, we created a playback track of 90 min to encompass the 30-min acclimatization period and the 60-min foraging period.

For the anthropogenic noise condition, we supplemented the ambient-noise playback track with motorboat noise at various Signal-to-Noise Ratios (SNRs) using Audacity® software 2.2.1. The original boat recording was 45-sec long and corresponded to the passage of a small fishing boat with an outboard engine (see Alves et al., 2016 for further detail). We applied a linear fading on both ends of the boat noise to make it emerge from the ambient noise. To provide a substantial acoustic stimulation, the boat noise was looped four times into a ‘noise sequence’ of 3 min and we broadcasted eight noise sequences interspersed with ambient noise over the 1-h foraging period. Within each noise sequence, we varied the SNR between the four boat noises to mimic a fleet of four boats passing successively at various distances. To avoid fish habituation to the noise or the rhythm, we varied the SNRs and the time intervals between the noise sequences (Table 1).

The tracks were played back as WAV files using an audio player (VLC media player 1.1.8), an amplifier (Yamaha RX-V540RDS), and the underwater speaker. To calibrate sound pressure within the aquarium, we placed the hydrophone used to record the ambient noise in the center of the aquarium and adjusted the intensity of the amplifier to have the same Root-Mean-Square (RMS) sound pressure than in the center of the housing tank. Then, to generate the SNRs of 2, 4 and 8, we adjusted the RMS sound pressure of the boat noise to have 2, 4 or 8 times the RMS value of the ambient noise. Minnows have been shown to respond behaviourally to tones up to 5 kHz (Dijkgraaf & Verheijen 1950, Voellmy et al., 2014), where the frequency spectrums of the ambient noise and the boat noise differed (Fig. 1). We therefore expected the minnows to respond differently to the two noise conditions.

2.4 Behavioural measurements
Behaviour was recorded over the 8 successive noise sequences, where fish experiencing the anthropogenic noise condition were exposed to the boat noise while those experiencing the control condition were exposed to the ambient noise. The swimming distance covered during the 3 min of each noise sequence was assessed by visual tracking using a software (Mousotron 12.1, Blacksun Software), a video player (VLC media player 1.1.8) and the above camera. To measure spatial distribution, we used the front camera and virtually divided the aquarium into two equal areas: left versus right to test noise aversion, the speaker being in the left area, and bottom versus top for the position along the water column. Position was recorded every 15 sec during the 3 min of each noise sequence and we assigned the value of ‘0’ when the fish was in the left or the bottom area, and the value of ‘1’ for the right or the top area. At the same time, we also measured the distance to the companion fish (head to head) to assess social interactions.

2.5 Statistical analyses

We used the R software (version 3.5.1, R Development Core Team 2017) with a significance level of 0.05 for all the statistical analyses. Fish size being not normally distributed for the control noise condition (Wilk-Shapiro test, \( P = 0.011 \)), we tested the difference in fish size between the two noise conditions using a Wilcoxon-Mann-Whitney test.

Functional response (FR) analysis was done with the ‘frair’ package (Pritchard et al., 2017). The first step was to investigate which FR model between the types I, II and II best described our data using the ‘frair_fit’ function where the model is optimized using the maximum likelihood estimation (MLE). The simple type I (or linear) FR (‘fr_typel’ in ‘frair’) is implemented as:
\[ N_e = aN_0T \]

where \( N_e \) is the number of prey eaten, \( N_0 \) the initial prey density, \( a \) the attack rate and \( T \) the total experimental time.

For the type II FR model, we used the Rogers’ random predator equation (‘fr_rogersII’ in ‘frair’), which is a modified version of the Hollings’ original type II FR dedicated to non-replacement experiments. The number of prey eaten (\( N_e \)) follows the relationship:

\[ N_e = N_0(1 - \exp(a(N_e h - T))) \]

where \( N_0 \) is the initial prey density, \( a \) the attack rate, \( h \) the handling time and \( T \) the total experimental time. Model fitting was achieved using the Lambert’s transcendental equation (Bolker, 2008, ‘lambertW0’ function from the ‘lamW’ package).

For the type III FR model, we used the Hassel’s type III extension to the Roger’s random predator equation (‘fr_hassIIIinr’ in ‘frair’). The number of prey eaten (\( N_e \)) follows the same relationship defined for the Rogers’ type II model except that the attack rate (\( a \)) is assumed to vary with prey density in the following hyperbolic relationship:

\[ a = \frac{bN_0}{1 + cN_0} \]

where \( b \) and \( c \) are coefficients to be fitted and \( N_0 \) the initial prey density.

We compared the fits using the second order Akaike criterion (AIC), considering that the best model is the one having the lowest AIC and that a delta AIC lower than 2 between two fits means that both corresponding models perform as well (Nakaya et al., 2005). In addition to the AIC approach, we also used the ‘frair_test’ function to specifically decide between the type II and type III models. The idea is to fit a polynomial logistic function to the proportion of prey consumed, a logistic regression being more able than a non-linear curve to detect the subtle difference in curve shape at low prey densities between the type II and type III models (Juliano, 2001; Pritchard et al., 2017). A type II FR is characterized by a
299 significantly negative first order term and a type III FR by a significantly positive first order
300 term followed by a significantly negative second order term (Juliano, 2001).
301 Once the best model identified, the second step was to generate 95% confidence intervals
302 (CIs) of the FR parameter estimates. This was done by non-parametric bootstrapping ($n =
303 2000$) with the ‘frair_boot’ function.
304 Finally, the third step was to test the between-treatment difference in the FR fit. The
305 type II FR being the best model for both treatments, the FR comparison came down to a
306 comparison of its two constituent parameters: attack rate $a$ and handling time $h$. This allowed
307 us to use the delta (or difference) method provided by the ‘frair_compare’ function that tests
308 whether $Da$ and $Dh$ (the differences in attack rates and handling times) significantly differ
309 from zero (Juliano, 2001; Pritchard et al., 2017). In addition to the delta method, we inspected
310 the overlapping of the CIs of $a$ and $h$ provided by the ‘frair_boot’ function. To compare the
311 FRs at intermediate prey densities where a difference would not be detected by the delta
312 method (see Pritchard et al., 2017), we inspected the overlapping of the 95% CIs when plotted
313 on the entire FR curves with the ‘drawpoly’ function.
314
315 We aimed at estimating the strength of the noise effect on behaviour and its variation
316 during the course of the experiment. For this, we performed an exploratory analysis on the
317 four behavioural traits (swimming distance measured continuously during each noise
318 sequence, average distance to the companion fish obtained from the 12 measures taken during
319 each noise sequence, horizontal and vertical positions assessed 12 times at each noise
320 sequence). Linear and generalized linear mixed-effect models were used to model the
321 response variables of fish behaviour as a function of the noise treatment taking individual fish
322 as a random factor. Measurement period (i.e. the eight successive noise sequences), fish size
323 and prey density were treated as covariates that potentially affect fish behaviour. Trend in fish
324 behaviour during the course of the experiment is part of within-individual variation and can
change under the effect of noise. This was modeled by including a Treatment × Period interaction term in the model. The full model we fitted was on the general form:

\[ Y_{ij} = Treatment_{0/1} + b_{0/1} Period_j + c_{0/1} Period_j^2 + d FishSize_i + g PreyDensity_k + (ID_i) + \varepsilon_{ijk} \]

where \( Y \) is the response variable, Treatment is the treatment effect including ambient noise [0] and boat noise [1], Period denotes the change in behaviour through time quantified by a linear coefficient \( b \) and a quadratic coefficient \( c \) (included because visual explorations of the data suggested a quadratic relationship with time). These coefficients are likely to be affected by the effect of boat noise: the contrasts \( b_1 - b_0 \) and \( c_1 - c_0 \) quantify the Treatment × Period (i.e. behavioural change during the course of the experiment due to the noise treatment) linear and quadratic interactions, respectively. FishSize and PreyDensity are covariates whose effects are quantified with their respective coefficients (\( d \) and \( g \)), ID is a random factor for fish identity, and \( \varepsilon \) is within-individual residual variation. Intercept of the model was fixed at the average of the control group. Swimming distance and distance to the companion were treated as a Gaussian response by linear mixed-effects models while horizontal (the sound coming from the left end of the aquarium) and vertical positions were treated as binomial responses (with a Logit link function) by generalized linear mixed-effect models. In order to make parameter estimates directly comparable as effect sizes; input variables were centered and standardized according to the recommendations of Gelman (2008). We then obtained standardized effect sizes comparable across predictors.

We investigated a subset of the best models nested in the full model using an information-theoretic approach based on small sample-corrected AIC values (AICc) for model ranking. The models were fitted by maximum likelihood in the lme4 R package (Bates et al., 2014) and compared with the MuMln R package (Barton, 2018). Parameter estimates were obtained from a model averaging approach following the procedure recommended by
Grueber et al. (2011). We interpreted the “full” average coefficient that set to zero the coefficient absent from one model. This approach is expected to be the most conservative as the value does not tend to be biased away from zero (Barton, 2018). The top model set selected for model averaging included the models presenting a ΔAICc of less than ten with the best model, a conservative threshold suggested by Bolker et al. (2009).

2.6 Ethical notes

Electrofishing was conducted by Pierre Grès from the Fédération de Pêche de la Loire and fish were returned to the stream at the end of the experiment. All procedures described in the manuscript were conducted in accordance with appropriate European (Directive 2010/63/EU) and French national guidelines, permits and regulations regarding animal care and experimental use (Approval n°C42-218-0901, ‘Direction Départementale de la Protection des Populations’ committee, Préfecture du Rhône).

3 RESULTS

All the Chaoborus sp. larvae survived in the replicates without fish, suggesting that larvae removal during the experiments was the result of fish predation. There was no significant difference in fish size between the two noise conditions (Wilcoxon-Mann-Whitney test, \( P = 0.214 \)). Based on the AIC values and for both noise conditions, the type II and type III functional response (FR) models performed as well (ΔAIC < 2) and better than the type I (Table 2). Using the logistic regression of the proportion of prey consumed against prey density, the first order term was significantly negative for both noise conditions (ambient noise: 1st order term = -0.030, \( z = -2.968, P = 0.003 \); boat noise: 1st order term = -0.024, \( z = - \)
2.433, \( P = 0.015 \), which suggested to choose the type II over the type III (Fig. 2). Based on
the delta method, there was no significant difference in the handling time \( h \) between the two
noise conditions (\( Dh = 0.001, z = 0.166, P = 0.868 \)) but the attack rate \( a \) was significantly
lower with the boat noise compared to the ambient noise (\( Da = 0.835, z = 2.815, P = 0.005 \)).
Consistently, the confidence intervals (CIs) fully overlapped for handling time and partly
overlapped for attack rate (Fig. 3). When looking at the CIs of the fitted curves (Fig. 2),
variability was higher with boat noise compared to ambient noise.

The results of model averaging to investigate the behavioural responses of fish to
noise are summarized in Table 3. Although on average, boat noise had no effect on swimming
distance and distance to the companion fish, it altered their pattern of response through time
as both the linear and the quadratic components of the relationship with time differed between
noise treatments (Table 3, A & B). The maximum swimming distance recorded during the
course of the experiment peaked consistently higher in the boat noise treatment than in the
ambient noise treatment, indicating that boat noise increased the maximum swimming
distance covered by fish (Fig. 4A). We observed the opposite effect for the distance to the
companion fish, whose maximum value was decreased by boat noise during the course of the
experiment (Fig. 4B). Fish occurrence at the left side of the aquarium (the opposite side of the
speaker) was positively influenced by boat noise and by fish size (Table 3C). Fish occurrence
at the top area of the aquarium increased with time regardless of the noise condition (Table
3D).

As we found an effect of boat noise on both behaviour and predation, we conducted an
a posteriori investigation to further explore the link between them and try to explain how
behavioural responses to noise might result in reduced predation. The proportion of prey
consumed was negatively influenced by prey density and boat noise, which is rather logical
for prey density (the range of prey densities is chosen so as to reach predator saturation) and
consistent with FR results for boat noise, but we did not find any effect of the four
behavioural variables (Supplementary Table S1).

4. DISCUSSION

We used the functional response (FR) approach to test the effect of anthropogenic noise on
the trophic interaction between the European minnow *Phoxinus phoxinus* and one of its
potential prey, the dipteran larva *Chaoborus* sp.. As expected and consistently with the FR
displayed by other fish species in shelter-free experimental arenas (Alexander et al., 2014,
2015; Laverty et al., 2017), the FR of *P. phoxinus* for both noise conditions was found to be
of type II, in which predation rate rises with prey density at a decelerating rate to an upper
asymptote. Type II FRs are considered destabilizing because of the high proportion of prey
consumed at low densities, potentially leading to prey exclusion. However, more realistic
conditions like predator learning, the presence of alternative prey with prey switching, or
habitat complexity with predator – free areas can decrease predator’s efficiency at low prey
densities and generate the less destabilizing type III FR (Alexander et al., 2013; Barrios-
O’Neill et al., 2015). We therefore cannot claim the FR of *P. phoxinus* towards *Chaoborus* sp.
larvae to be also of type II in the field.

Adding motorboat noise to ambient noise did not change handling time and therefore
maximum feeding rate (1/h), resulting in the same asymptote, but decreased attack rate,
resulting in a less steep initial slope. This is consistent with our assumption of a greater effect
on attack rate than on handling time, the former depending mainly on behaviour and the latter
more on physiological and morphological constraints. This also suggests that minnows,
conversely to other species like the three-spined stickleback (*Gasterosteus aculeatus*) (Purser
& Radford, 2011) or the fathead minnow (*Pimephales promelas*) (Hasan et al., 2018), were
not distracted by noise and consequently did not take more time to handle and ingest their prey.

The swimming distance of minnows was significantly increased by boat noise, which may at first sight seem contradictory with the increased inactivity reported by Voellmy et al. (2014) with the same fish species. However, the authors did not measure swimming distance and they found more startle responses (i.e. sudden movement at high speed) for exposed fish. It follows that even if minnows were overall less active under boat noise, a higher mobility during activity periods cannot be excluded. If we assume that attack rate increases with predator mobility (Gerritsen & Strickler, 1977), a relationship that our experimental design has not allowed to verify (4 replicates only), then we might have expected a higher attack rate with boat noise in the present study. The reduced attack rate we observed might therefore reflect a lower feeding motivation. In accordance with the results of Voellmy et al. (2014), boat noise promoted social interactions as suggested by the significant decrease in distance to the companion fish. Anthropogenic noises are known to trigger anti-predatory responses (Frid & Dill, 2002; Rabin et al., 2006) and minnows form shoals under predation risk in structurally simple habitats (Orpwood et al., 2008). The social proximity we observed might reflect this anti-predatory response. Whatever the noise condition, fish occurrence in the upper area of the aquarium increased with time, which is probably because they swam more and were more exploratory as they got familiar with their environment. Fish were found more often at the opposite side of the speaker (right end of the aquarium) with boat noise than with ambient noise. Because noise level slightly decreased with distance to the speaker in our aquarium (result not shown), the preference for the opposite side of the speaker might reflect avoidance of the sound source. Whatever the noise condition, fish presence at the opposite side of the speaker was positively influence by fish size. Considering that large fish are older and more experienced than young fish (Chivers & Smith, 1998), this might result from the greater
wariness of large fish towards the speaker, viewed as an unfamiliar object. Besides the
reduced feeding motivation that could be associated with escape response and from a more
functional perspective, alterations in predators’ distribution are likely to change spatial
overlap with prey and therefore predator – prey encounters. This might have contributed to
the decreased attack rate observed with boat noise.

When considered together, the behavioural changes we observed suggest a more
general stress-related response whereby fish feed less, move to avoid the areas of elevated
noise level, and group with conspecifics as they could do under predation risk. Interestingly,
the strength of the negative effect on predation depended on prey availability, with a stronger
effect at low densities. Both swimming and foraging are costly and the cost of foraging is
high when prey are scarce. Therefore, at low prey densities, exposed fish might have allocated
less time to foraging to offset the additional cost of the stress response. At the opposite, when
prey were abundant, the cost of foraging was low and exposed fish might have been able to
engage in both activities concurrently.

Between-individual variability in behaviours was higher with boat noise than with
ambient noise as revealed by the wider confidence intervals of the FR parameters and the FR
curves. Personality differences are a common feature of animal populations (Wolf &
Weissing, 2012; Mittelbach et al., 2014) and individuals often vary along a shyness –
boldness continuum. It could be that personality differences are exacerbated by the stress
induced by anthropogenic noise.

Our setup did not allow us to record and analyze the behaviour of Chaoborus larvae
and their reaction to noise could have contributed to the observed decrease in attack rate.
Invertebrates can perceive and use sounds (e.g. Solé et al., 2016) and their susceptibility to
anthropogenic noise raises a growing interest (Morley et al., 2014). For instance, elevated
sound level has been found to differentially affect the abundance of terrestrial arthropods
When exposed to playback of ship noise, the shore crab *Carcinus maenas* shows disrupted feeding and antipredator behaviours (Wale et al., 2013a), and stress-related physiological responses (Wale et al., 2013b). Conversely, Sabet et al. (2016) did not find evidence for a negative effect of elevated sound level on the swimming behaviour of water fleas (*Daphnia magna*). *Chaoborus* larvae have flagellar mechanosensory structures (Giguère & Dill, 1979) that make them sensitive to particle velocity (Morlay et al., 2014), the other component of a sound wave with pressure waves. They are thus able to perceive anthropogenic noises and might have reacted differently between ambient noise and boat noise. As an adaptive anti-predatory response, *Chaoborus* larvae exhibit vertical migrations and move to deeper strata in the water column where detectability by visual predators is reduced (Dawidowicz et al., 1990; Christjani & von Elert, 2015). Fish presence triggers the vertical migration and the stimulus is chemical. If anthropogenic noise was perceived as predation threat by *Chaoborus* larvae, then it might have triggered migration to the bottom, thus contributing to the decrease in attack rate.

Whatever the underlying mechanisms driving the change in FR, our finding suggests that anthropogenic noise has potential to decrease the strength of trophic links, which might have population and community outcomes. From the predator's perspective, less energy input would ultimately induce a fitness cost, which can be offset by adjusting foraging patterns. For instance, the Mediterranean damselfish *Chromis chromis* was found to reallocate its foraging effort during the periods of low traffic intensity (Bracciali et al., 2012). As suggested by the avoidance of the speaker in the present study and as reported in the literature, predators can also leave the foraging areas of elevated sound level to find more quiet feeding patches (Miksis-Olds & Wagner, 2011), which can go with alterations in diet composition (Payne et al., 2015). The distribution of interaction strengths within a community depends on consumers’ diet and influences stability. Theoretical investigations have indeed demonstrated
that a skewed distribution pattern with a few strong links (i.e. with a high predation rate) for a
majority of weak links, which is common in nature, promotes stability compared to a more
homogeneous distribution (McCann et al., 1998; Rooney & McCann, 2012). Further
experiments are needed to test the effect of anthropogenic noise on the distribution of
interaction strengths and stability. From the prey’s perspective, predation release can
influence lower trophic levels depending on the position of the prey along the food chain. For
instance, *Chaoborus* sp. larvae are natural predators of water fleas (Pastorok, 1981) and the
reduced vulnerability to fish predation under elevated noise level might have a negative
indirect effect on water fleas. Very recently, Barton et al. (2018) have experimentally
demonstrated the cascading effect of noise pollution along a beetle – aphid – plant tri-trophic
food chain but, to our knowledge, this is the only study that formally addressed this issue.

To conclude, our study provides additional evidence for the negative effect of
anthropogenic noise on predation and shows the usefulness of the functional response
approach to study the ecological impact of noise. We need further experiments involving
more interacting species and designed under the conceptual frameworks of community
ecology and food-web theory to decipher how individual responses to noise spread through
community to ultimately alter ecosystem properties. Chronic-exposure investigations are also
welcome to test for the long-term effects of noise persist as some species have been shown to
habituate to noise (Jacobsen et al., 2014; Johansson et al., 2016; Magnhagen et al., 2017).

**ACKNOWLEDGMENTS**

We thank Pierre Grès from the fédération de pêche de la Loire for help during fish collection
and the University of Saint Etienne for fundings. **We also thank the two anonymous reviewers**
for their helpful comments on the previous draft of this manuscript.
CONFLICT OF INTEREST STATEMENT

No conflict of interest declared.

FIGURE CAPTIONS

Figure 1: Spectral density of the audio signals used to create the two noise conditions. The original audio signals and their re-recordings in the experimental setup are represented with discontinuous and solid lines, respectively. European minnows have been reported to react to frequencies up to 5 KHz.

Figure 2: Number of prey eaten as a function of prey density (functional response) for European minnows (*Phoxinus phoxinus*) feeding on dipteran larvae (*Chaoborus* sp.) in two noise conditions: ambient noise alone (control treatment, in blue) or supplemented with motorboat noise (anthropogenic noise treatment, in red). Dots are direct observations and curves are the functional responses fitted with the ‘frac’ package (Pritchard et al., 2017). Shaded areas represent bootstrapped (*n* = 2000) 95% confidence intervals.

Figure 3: Estimates of the functional response parameters: attack rate and handling time, for European minnows (*Phoxinus phoxinus*) feeding on dipteran larvae (*Chaoborus* sp.) in two noise conditions: ambient noise alone (control treatment) or supplemented with motorboat noise (anthropogenic noise treatment). Error bars represent bootstrapped (*n* = 2000) 95% confidence intervals.

Figure 4: Change in swimming distance (a) and distance to the companion fish (b) according to experimental time (evenly spaced across eight successive measurement periods) for European minnows (*Phoxinus phoxinus*) feeding on dipteran larvae (*Chaoborus* sp.) and exposed on ambient noise (control) or boat noise.

Supplementary Table S1: Summary results of model averaging for the proportion of prey consumed. The full model we fitted was on the general form:

\[ Y_{ijk} = Treatment_{[0/1]} + b \text{PreyDensity}_j + c \text{PreyDensity}_j^2 + d \text{FishSize}_i + f \text{VertLocation}_[{B/T}] + g \text{HorLocation}_[{L/R}] + h \text{TotalDistance} + k \text{DistanceCompanion} + \epsilon_{ijk}, \]

where \( Y \) is the response variable, \( Treatment \) is the binary treatment effect including ambient [0] and boat [1] noise, \( PreyDensity \) and \( FishSize \) are covariates, \( TotalDistance \) is the cumulative swimming distance covered across the eight periods of recording, \( DistanceCompanion \) is the average distance to the companion fish calculated from the 96 recordings (12 measurements for each of the eight recording periods), \( HorLocation \) is the proportion of recordings on the right side of the aquarium, \( VertLocation \) is the proportion of recordings on the top area of the aquarium, \( \epsilon \) is residual variation. The coefficients \((b, c, d, f, g, h \text{ and } k)\) quantify the strength of the effects. The analysis of a more complex model (not shown) including the interactions between the noise treatment and the four behavioural variables did not allow to detect any interaction effect.
